#### Abstract

This paper aims to contribute for the understanding of factors measuring mothers' educational levels on under-five children mortality from developing countries in South East Asia. Because extremely poverty remains a huge challenge in the South East Asia's developing countries. Set of factors related to socio-economic status on children survival. My study chose under-five mortality because it can influence infant and underone mortality as well as Millennium Development Goals (MDG)'s indicator. My study of regression confirmed a strong association between mother's education and under-five child mortality and remained significant after control for other factors.

The result imply that big part of the effect of mothers' education levels (primary, secondary and tertiary) can be substituted by investing than other factors. Investment of girls' schooling is still one of the essential ways to contribute for child survival improvement in the long run because the findings of this research agree that "Mother is school". On the other hand, the study of these areas will sustain the vital two sectors from policy makers. This paper was established that mothers' education has a negative impact on children mortality mostly; policy makers in region will have to focus their efforts on enhancing investment of education sector and reducing under-five child mortality by improving the performance of female education in these regions.

## ACKNOWLEDGEMENTS

First and foremost I would like to express my earnest gratitude to my supervisors Prof. Seulki Choi and Prof. Changyong Choi. I really appreciate for the inspiration from their guidelines, the encouragement and constructive comments which received during research thesis paper writing.

I am always grateful to my beloved parents and my sister because of their unbounded help and hind encouragement. And I appreciate to Dr. Wah Wah Maung - my Director General from Central Statistical Organization (CSO) of Myanmar for the permission and giving opportunity to attend this school, Mr. Kitada San - Director from SIAP in Japan who encouraged me to do this work, Professor Dr. Hnin Hnin Oo - Head of Mathematics Department of Kyaing Tong University and Professor Dr. Basu from ISEC of India who raised me with their hands wherever I need them.

I also thank to my mutual friends and their supports. Without all of you, my stay at KDI cannot be. This chance would not have been created without the financial support from KOICA. Therefore, I am highly thankful to the founders and faculty members of KOICA-MDI Organization.

## I. INTRODUCTION

### 1.1. Background of the Study

Although some South East Asia countries had already developed, most of South East Asian countries were as developing countries. Moreover, extremely poverty remains a huge challenge in the South East Asia countries as Least Development Countries (LDCs). Therefore, income and demographic characteristics has widened continuously with developed countries in region. R. Fuchs, W. Lutz and E. Pamuk mentioned that different policy implications approved especially with respect to reducing child mortality in developing countries although most studies regarded education and income as interchangeable measures of socio-economic status. Because mothers' levels of schooling and learning performance can improve the children' lives as well as decrease child mortality. Although we have various kinds of indicators for child mortality, I chose underfive mortality because it can influence infant and under-one mortality as well as Millennium Development Goals (MDG)'s indicator. At the same time, survival children will be the next generation for sustainable growth. Therefore, developing countries in South East Asia should try to reduce the children mortality for the future inclusive growth.

### 1.2. Statement of the Problems/issues

There is need to establish evidence of the effect of mothers' education on underfive mortality in South East Asia's developing countries. Most of developing countries have several challenges and many issues such as lack of infrastructure, lack of knowledge, lack of budget and inefficiency. Moreover, absence of actual statistics, policy maker met the failed planning for growth especially education and health sectors. For inclusive growth, these two sectors are very fundamental sectors. Therefore, filling the gap is beneficial to both their governments and their citizens within region. Since there is general
issue on the child mortality, establishing evidence on whether mothers' education will contribute inclusive development efforts in the South East Asia's developing region. If it is established that mothers' education has a negative impact on children mortality, policy makers in region will have to focus their efforts on enhancing investment of education sector. If the evidence proves otherwise they will think to adjust their investment policies in the region.

### 1.3. Purpose of the Study

This study can support between decision makers and citizens to fulfill citizens' lives indirectly by government policy because child survival is often used broad indicators for social development. Moreover, maternal education is important for health of children
to improve of the country's growth. Mothers' routine decisions can influence child health. Therefore, the very research can promote socio-economic status by studying the effect of maternal education on child survival especially under-five mortality which is to be sustainable growth in South East Asia.

### 1.4. The Objectives of the study

1. To monitor the demographic variables in South East Asia developing countries on child mortality in the age of under-five years
2. To identify the relative importance of the levels of mothers' education and underfive child mortality
3. To encourage female educational levels and mothers' knowledge to possess the qualified children who be the human capital in future growth

### 1.5. Research questions

- What is the effect of mothers' education on the under-five mortality of developing countries in South East Asia?
- How do we reduce under-five child mortality in these regions?

### 1.6. Study Hypothesis

The developing countries of South East Asia are expected to be positive by the effect of mothers' education on child mortality and regardless of the prevailing policy distortions in the individual countries within the region. Nevertheless policy and institutional quality is expected to enhance the effect of mothers' education. With this argument and our research questions in mind, a hypothesis is made that under-five child
mortality is associated with mothers' educational levels than other factors in South East

## South East Asia's developing countries.

### 1.7. Structure of the Paper

This paper is made up of the followings. Chapter 2 will be presented by literature review and chapter 3 will discuss theoretical framework and chapter 4 is the methodology with collecting data, specification of the conceptual models and definitions of the variables used and interpreting. Chapter 5 will add discussion with the findings and reflection. Finally, chapter 6 will include conclusions.

## II. LITERATURE REVIEW

### 2.1. Theoretical Background

Population size and population growth of a country are thought by variables for economic growth and that, a mother's education is essential for child survival. The study of the determinants of child survival plays a vital role on both social and biological variables in developing countries. The mother's quality of care is very important during pregnancy and child birth by nutrients management. The mother is the most important health care provider of her baby. The mother's empowerment can influence a child's health. It is hypothesized that a mother's education is essential for child survival. The following literature reviews support this hypothesis.

### 2.2. The Impact of Population Size and Population Growth

This research examined the impact of population size and population growth on the quality of the health of mothers and their children. As indicated in a research article by Bash (2015), census has important ramifications for many aspects of society and can be an examined parameter in research involved in demographic analysis of the population. Bash further investigates some limiting factors which avert population growth and examines the differences in the results of the same period using different models. The research design, the study area, data collection methods and instruments, validation of the instruments, limitations and the procedure for data analysis were discussed.

### 2.3. The Effect of Maternal Education on Child Survival

Lillard, Simon, Ueyama (2007) indicated that a mother's high school education improves a mother's age at child's birth including child care use. They also discovered suggestive evidence of a much more complex set of behaviors that are causally related to maternal education and that likely affect child health.

This preliminary evidence suggests that the very study can strongly conclude the child health by maternal education. The body of empirical evidence showed that not only education can improve health but also that health can affect education.

Researchers in this field have used many methodologies; one of the methods used is the instrument variables. With this methodology, researchers have found that, in developing countries generally, education concerned with better child health. According to the researcher's result, when women get more education, child survival (Breierova and Duflo 2004; Blunch 2005) and children's height-for-age increase (Ahmad and Iqbal 2005). Many researchers generally agree that, the relationship between education and health is a main point input to several continuing public policies in all economy contexts.

### 2.4. The Relationship between Child Survival and a Mother's Health Based Socioeconomic Status as Variables

Usually, social science research on child mortality has engrossed on the suggestion between socioeconomic status and levels and designs of mortality in populations. Chen and Mosley (1984) proposed the learning of the determinants of child survival on both social and biological variables in developing countries. The purpose of the child survival study is to illuminate our sympathetic of the many factors involved in the family's production of healthy children in order to deliver a foundation for framing health policies and strategies. The strategic to the model is the sympathy of a set of
adjacent determinants, or intermediate variables, that directly impact the risk of morbidity and mortality. Each of the maternal factors has been exposed to use an independent influence on pregnancy results and infant survival through its effects on maternal health. An important inclusion is the performants and the quality of care during pregnancy and childbirth. The significance of this research is correlations between mortality and socioeconomic characteristics for the mortality causes. For example, income and maternal education are two generally measured correlates (and inferred causal determinants) of child mortality in a developing nation population. All social and economic determinants must activate through these variables to affect child death.

### 2.5. Long Term Effect of Maternal Education on under-five child mortality

Child health is one of the main indicators of development of a country. Hassan (2014) contributed to understanding the long term effect of maternal education on underfive child mortality (U5MR).The relevance of this research stems from the fact that, asset in girls' schooling is still one of the important ways to contribute not only child health development but also growth in the long run. Hassan's paper examined the factors causal child health by investigating the effects of maternal education on the event of under-five mortality. This paper indicated the set of factors related to socio-economic status including the use of health care service area; reproductive behaviors of women; mothers' empowerment; and parental employment status. These were comprised in the regressions with the aim to catch the partial effect of maternal schooling on the incidence of underfive mortality.

Instead, various other variables were tried for their mediation on the outcome of maternal education on under-five mortality. These included maternal characteristics such as family prosperity index, pre-birth interval, types of floor materials, sanitation facilities,
drinking water, staying health facilities, modern contraceptive use, antenatal visit, and delivery in health conveniences. The author used the Linear Probability Model (LPM) regressions and the pooled regressions with DHS survey for Ethiopia country which indicated that the mean of the incidence of under-five child mortality decreased significantly in the period of 2000 to 2011. It similarly reduced with increasing levels of maternal education. Likewise, significantly higher mean of years of schooling was attained for surviving mothers' children.

### 2.6. The Relationship between Maternal Education and Child Survival based Spatial Demographic Analysis

Weeks (2001) suggested for the application of spatial analysis to demographic research as a method to integrate and superior understand the unlike transitional apparatuses of the whole demographic transitions especially the fertility transition in Egypt. The authors argued in the context of a analysis of the still reasonably sparse literature on spatial analysis in demography and then turns to the sorts of data that are required for spatial demographic analysis; the kinds of statistical methods that are accessible to researchers; and the approach in which Geographical Information System (GIS) can support to integrate each of these components for the theories testing and models building. So, demography is not only spatial but also by nature interdisciplinary. The overall transition in population size can occur when mortality drops sooner than fertility (the common pattern in the demographic transition) from which massive variations follow with respect to resource utilization and allocation. This paper hypothesis is how and why these transitions occur.

Many demographic researches, engages spatial "analysis". Research that incorporates spatial information recognizes that demographic behavior will differ by
geographic region that population characteristics and change are unlike in urban than in rural places. The spatial analysis application to demographic research is a method of integrating and enhanced understanding of the different transitional components of the overall demographic transition.

Weeks also discussed the kind of data required for spatial demographic analysis, permitting researchers to use the concepts and tools of spatial analysis to test theories increasing out of the general framework. He also summarized the research for an upgraded understanding of the Arab fertility transition through the challenging of explicitly spatial hypotheses about the timing and tempo of fertility change.

Weeks's paper achieves with an example of this type of research, sketch upon the author's study, which is expected at a better understanding of the Arab fertility transition through the testing of explicit spatial theories about the timing and tempo of fertility change. Definitely, this research relates GIS, remote sensing, and the relationship between spatial statistics and the fertility transition in rural and urban Egypt. Additionally as indicated above, the use of spatial analysis to demographic research must be updated by accepting the different transitional components of the whole demographic transitions especially the fertility transition.

## III. THEORETICAL FRAMEWORK

### 3.1. Mosley-Chen's Conceptual Model of Mortality

The model recommends combining social science and medical science research methods in dealing with infant and child mortality factors in developing countries. The following is broadcast mechanism of the model.

Figure 1: Conceptual Framework of Child Mortality [Source: Mosley and Chen (1984)]

### 3.2. Leroy Almendarez's Human Capital Theory <br> Leroy Almendarez (2011) purposes Human Capital Theory (HTC) which

 determines that investment in human capital will hint to great economic outputs but the validity of the theory is sometimes tough to demonstrate and contradictory. At one time, economic strength was mainly depended on real physical assets such as land, factories and equipment. Now a days, Beckr (1993) supports modern economists appear to concur that education and health care are the significant to improving human capital and ultimately growing the economic outputs of the nation. He argues that Human Capital Theory (HCT) is the most persuasive increasing the economic theory of western education, situation the framework of government policies since the early 1960s and it is gradually seen as a key determinant of economic performance.Literature has indicated generally that the more educated mothers are superior for absorbing the benefits of health infrastructure and health knowledge that are universally accessible. Research has also indicated that giant part of maternal education can be replaced by advancing in other factors that can improve socio-economic status, use of health amenities, and health behaviors of women (Weeks, 2001).The extent to which maternal education affects child survival can vary across various sectors of society and within countries and also the direction of causation varies. The purpose of this study is to simplify our understanding of the many factors complicated in the family's manufacture of healthy children in order to afford a foundation for framing education policy and strategies.

Therefore, this study builds on the strengths of the studies like that Uzma Iram (2013) who focused a panel of world developing countries which are middle low income. We attempt to overcome the other studies discussed in the literature review which make general conclusions based on samples that are too broad. We believe the South East Asia's developing region is reasonably homogeneous to be studied together over some time span and make generalized conclusions. We further recognize the need to address the evidence of the effect of mothers' education on under-five child mortality in South East Asia's developing countries as done by Uzma Iram (2013).

## IV. METHODOLOGY

### 4.1. Conceptual Framework

Although both maternal and paternal education are among the socio-economic factors that affect child mortality, mothers' education has been one of the main factors of child health indicators and child mortality in many studies specially. The following diagram (Figure 2) is drawn based on the above discussion and it shows the way mothers' education can affect under-five mortality. It shows its direct effect and indirect effect and employs through other factors.

Figure 2: Conceptual Framework of Child Mortality
Given the nature and characteristic of the problem under investigation in this paper, it is prudent to use linear panel data regression methods to evaluate the effect of mothers' education on under-five child mortality in South East Asia countries. This panel data is a dataset in which the comportment of entities observed across time. These entities could be developing countries in South East Asia for this paper. Panel data permits me to control for variables I cannot see or measure like cultural factors or variables for individual heterogeneity. Furthermore, we can contain variables at different levels of analysis for multilevel modeling in panel data. We can center on two techniques
use to analyze panel data such as Fixed Effects (FE) or Random Effect (RE) estimations techniques for Error Component Model. We can use Fixed Effects (FE) whenever we only engrossed for analyzing of the impact of variables that vary over time. Moreover, FE can eliminate the effect of time-invariant characteristics thus we can measure the net effect of the predictors on the outcome variable as well as Fixed Effects (FE) models are considered to study the causes of changes within entity. Random Effect (RE), unlike the fixed effects model, agrees generalizing the inferences beyond the example used in the model. To select between fixed or random effects we can run a Hausman test where the null hypothesis is that the ideal model is Random Effect (RE) and the alternative the Fixed Effects (FE).

### 4.2. Model Specification

The baseline models specifically investigate the effect of mothers' education on under-five child mortality in South East Asia's developing countries takes the form:

```
\(\mathbf{U 5 M R}_{i t}=\boldsymbol{\beta}_{0}+\boldsymbol{\beta}_{1}\) Female (primary) Edu \({ }_{i t}+\varnothing X_{i t}+\varepsilon_{i t}\)
\(\mathbf{U 5 M R}_{\mathrm{it}}=\boldsymbol{\beta}_{0}+\boldsymbol{\beta}_{1}\) Female (secondary) Edu \({ }_{\mathrm{it}}+\varnothing \mathrm{X}_{\mathrm{it}}+\varepsilon_{\mathrm{it}}\)
U5MR \({ }_{i t}=\boldsymbol{\beta}_{0}+\boldsymbol{\beta}_{1}\) Female (tertiary) Edu \({ }_{i t}+\varnothing X_{i t}+\varepsilon_{i t}\)

For Overall Regression,
\(\mathbf{U 5 M R}_{i t}=\boldsymbol{\beta}_{\mathbf{0}}+\boldsymbol{\beta}_{1}\) Female (primary) Edu \({ }_{i t}+\boldsymbol{\beta}_{1}\) Female (secondary) Edu \({ }_{\text {it }}+\boldsymbol{\beta}_{1}\) Female (tertiary) Edu \({ }_{i t}+\varnothing \mathbf{X}_{\mathbf{i t}}+\boldsymbol{\varepsilon}_{\mathbf{i t}}\)

Where \(\mathrm{i}=1 \ldots \mathrm{~N}\) and \(\mathrm{t}=1 \ldots \mathrm{~N}\)
Under-five Mortality is dependent variable and independent variables are School enrollment, tertiary, female (\%), School enrollment, secondary, female (\%), School enrollment, primary, female (\%), Fertility rate, total (births per woman), GDP per capita
(current US\$), Improved water source (\% of population with access), Pregnant women receiving prenatal care (\%), Births attended by skilled health staff (\% of total), Health expenditure, total (\% of GDP), Improved sanitation facilities (\% of population with access), Immunization, measles (\% of children ages 12-23 months). The following definitions are variables for that study.

Main research of this paper is on the levels of school enrollment female variables.
As indicated in the hypothesis, we expect mothers' education levels to have negative impact on child mortality. The theoretical basis is that female schooling levels can affect the under-five child mortality in South East Asia's developing countries.

\subsection*{4.3. Limitations of the Study and Data Sources}

Universally, mortality studies are faced with data limitations, mainly in the developing countries in South East Asia where death is viewed as a sad affair that respondents do not love to recall because it brings back sad memories. The data limitations will stance a severe challenge to this study. The study therefore uses panel data for all sample variables of South East Asia's developing countries from 2000 to 2015, sources from the World Development Indicators (World databank).

\subsection*{4.4. Data Analysis with Panel Data}

According to analysis, we can see 14 variables and 272 observations and strongly balanced among panel variables for 17 developing countries in South East Asia from 2000 to 2015 year. Although most of countries' graphs showed negative relationship between under-five child mortality and year, there are still the highest mortality rates in the world.

First and foremost, my paper used the summary statistics for knowing minimum and maximum levels for variables as shown in figure.

\subsection*{4.4.1. Modeling under-five mortality rate on the female, primary school enrollment with}

\section*{Fixed Effects: Hausman Test}

Having decided to conduct panel estimation, we look another decision of whether to estimate our model with random effects (RE) or fixed effects (FE). The general approach to determining a more appropriate model between a fixed effects model and a random effects model is to conduct the Hausman Test. We therefore conduct the Hausman test for the female, primary school enrollment - under-five mortality rate model as shown in table 3 below. For Hausman test, null hypothesis that RE is appropriate and alternative hypothesis is FE is appropriate. The test generates a small Chi-square test statistic at 20.02 and a large p-value at 0.0103 . We therefore reject the null hypothesis that the difference in the coefficients generated by our model is systematic and accept the alternative. We therefore proceed to estimate a fixed effects model for the female, primary school enrollment - under-five mortality rate regression.

Table 3: Results of the Hausman test for the female, primary school enrollment - under-five

4.4.2. Results of the regressions for the female, primary school enrollment - under-five mortality rate

As stated in our hypothesis, we expect the female, primary school enrollment to effect on the under-five mortality rate by decreasing child mortality. Therefore we expect a negative relationship between for the female, primary school enrollment - under-five mortality rate. In Table 4 below, we will discuss the results which are estimated by regressing of under-five mortality on mothers' education levels and some control variables with pooled OLS and Fixed Effect (FE). Moreover, our interest is to see the changes in the magnitude and significance of the coefficient for variables. Then, we can claim the changes.

Table 4: Results of the regressions for the female, primary school enrollment - under-five mortality rate

\hline
\end{tabular}

Standard errors in parentheses
\[
* * * \mathrm{p}<0.01, * * \mathrm{p}<0.05, * \mathrm{p}<0.1
\]

In pooled OLS, a child from a mother with primary level of education is 0.476 percentage points less likely to die under the age of five. Then, a child from good sanitation facilities is 0.302 percentage points less likely to die under the age of five. Moreover, a child from getting immunization meals is 0.617 percentage points less likely to die under the age of five. The statistical significance levels of these are lower than \(99 \%\).

According to FE regression results, under-five mortality rate changes or increases 0.315 percentages, when the female primary school level decreases by one unit. When the improved
water source decreases by one unit, under-five mortality rate will change or increases 1.188 percentages.

The findings also indicate a strong effective and negative relationship between under-five mortality rate and them in these seventeen countries. This is also well expected and in line with theory. Moreover, our model is very good fit because the variables have significant influences on under-five mortality when the statistical significance levels of these are lower than \(99 \%\). We are happy about this model. I have no doubt about the result.

We can therefore conclude that indeed female primary school enrollment by increasing has helped in decreasing under-five mortality rate in these seventeen developing countries in South East Asia and to this effect female primary school enrollment has been very effective especially by model-1.

\subsection*{4.4.3. Modeling under-five mortality rate on the female, secondary school enrollment with Fixed Effects: Hausman Test}

For Table 5 Hausman test, null hypothesis that RE is appropriate and alternative hypothesis is FE is appropriate. The test generates a small Chi-square test statistic at 24.29 and a large pvalue at 0.0020 . We therefore reject the null hypothesis that the difference in the coefficients generated by our model is systematic and accept the alternative. We therefore proceed to estimate a fixed effects model for the female, secondary school enrollment - under-five mortality rate regression.

Table 5: Results of the Hausman test for the female, secondary school enrollment - under-five mortality rate regression

\subsection*{4.4.4. Results of the regressions for the female, secondary school enrollment - under-}

\section*{five mortality rate regression}

As stated in our hypothesis, we expect the female, secondary school enrollment to effect on the under-five mortality rate by decreasing child mortality. Therefore we expect a negative relationship between for the female, secondary school enrollment - under-five mortality rate. The results for that are shown in Table 6 below. Moreover, our interest is to see the changes in the magnitude and significance of the coefficient for variables. Then, we can claim the changes. As expected, our findings indicate a negative impact of secondary school enrollment for female on under-five child mortality in developing countries in SOUTH EAST ASIA.

Table 6: Results of regressions for the female, secondary school enrollment -under-five mortality rate regression
\begin{tabular}{lll}
\hline & \((1)\) & \((2)\) \\

& \((0.169)\) & \((0.234)\) \\
Constant & \(146.3^{* * *}\) & \(187.6^{* * *}\) \\
& \((17.21)\) & \((54.76)\) \\
Observations & 65 & \\
R-squared & 0.932 & 65 \\
\hline
\end{tabular}

> Standard errors in parentheses \(* * * \mathrm{p}<0.01, * * \mathrm{p}<0.05, * \mathrm{p}<0.1\)

In pooled OLS, when mother with secondary level of education increases by one unit, under-five mortality rate decreases 0.542 percentages. The statistical significance level of that is lower than \(99 \%\). Then, a child from improved water facilities is 0.341 percentages points less likely to die under the age of five. Moreover, a child from getting immunization meals is 0.414 percentages points less likely to die under the age of five. The statistical significance levels of these are lower than \(95 \%\).

According to FE regression results, under-five mortality rate changes or increases 0.017 percentages, when coefficient of the female primary school level decreases by one unit. When of the sanitation facilities decrease by one unit, under-five mortality rate will change or increases 0.901 percentages. The statistical significance level of that is lower than \(95 \%\).

The findings also indicate a strong effective and negative relationship between under-five mortality rate and them in these seventeen countries. This is also well expected and in line with theory. Moreover, our model is very good fit when probability value is significant. We are happy about this model. I also have no doubt about the result.

We can therefore conclude that indeed female secondary school enrollment by increasing has helped in decreasing under-five mortality rate in these seventeen developing countries in South East Asia and to this effect female secondary school enrollment has been very effective especially by model- 2 .

\subsection*{4.4.5. Modeling under-five mortality rate on the female, tertiary school enrollment with}

\section*{Fixed Effects: Hausman Test}

To determining a more appropriate model between a fixed effects model and a random effects model by conducting Table 7 the Hausman Test, null hypothesis that RE is appropriate and alternative hypothesis is FE is appropriate. The test generates a small Chi-square test statistic at 4.15 and a large \(p\)-value at 0.8434 . We fail to reject the null hypothesis that the difference in the coefficients generated by our model is not systematic. We therefore use to estimate a Random effects model for the female, tertiary school enrollment - under-five mortality rate regression.

Table 7: Results of the Hausman test for the female, tertiary school enrollment - under-five mortality rate

\section*{Regression}

\subsection*{4.4.6. Results of the regressions for the female, tertiary school enrollment - under-five mortality rate regression}

As stated in our hypothesis, we expect the female, tertiary school enrollment to effect on the under-five mortality rate by decreasing child mortality. Therefore, we expect a negative relationship between for the female, tertiary school enrollment - under-five mortality rate. The results for the female, tertiary school enrollment and under-five mortality rate regression are shown in Table 8 below. Moreover, our interest is to see the changes in the magnitude and significance of the coefficient for variables. Then, we can claim the changes. As expected, our findings indicate a negative impact of tertiary school enrollment for female on under-five child mortality in developing countries in South East Asia.

\end{tabular}

According to pooled OLS, when GDP per capital increases by one unit, under-five mortality rate decreases 0.0025 percentages. Then, a child from fertility rate is 5.055 percentages points more likely to survive under the age of five. The statistical significance levels of these are lower than \(95 \%\). A child from getting immunization meals and prenatal care are 0.698 percentages and 0.493 percentages points less likely to die under the age of five. The statistical significance levels of these are lower than \(99 \%\). Moreover, when sanitation facilities increase by one unit, under-five mortality rate decreases 0.311 percentages. The statistical significance level of that is lower than \(95 \%\).

In RE regression results, under-five mortality rate changes or increases 0.534 percentages, when coefficient of the female tertiary school level decreases by one unit. Then, a child from fertility rate is 5.678 percentages points more likely to survive under the age of five. The statistical significance levels of these are lower than \(95 \%\). A child from getting immunization meals and prenatal care are 0.420 percentages and 0.352 percentages points less likely to die under the age of five. The statistical significance levels of these are lower than \(99 \%\). Moreover, when sanitation facilities increase by one unit, under-five mortality rate decreases 0.117 percentages. The statistical significance level of that is lower than \(95 \%\).

The findings also indicate a strong effective and negative relationship between under-five mortality rate and these variables in these seventeen countries except the fertility rate. This is also well expected and in line with theory. Moreover, our model is very good fit when probability values are significant. We are happy about this model and no doubt about the result.

We can therefore conclude that indeed female tertiary school enrollment by increasing has helped in decreasing under-five mortality rate in these seventeen developing countries in South East Asia and to this effect female tertiary school enrollment has been very effective especially by model-3.

\subsection*{4.4.7. Findings of the overall female school enrollment regression model}

Table 9: Results of the regressions for the female school enrollment for all levels on under-five mortality rate
\begin{tabular}{ll}
\hline VARIABLES & \begin{tabular}{l} 
UNDER FIVE \\
MORTALITY
\end{tabular} \\
\hline Primary Female & \(-0.369^{* * *}\) \\

Standard errors in parentheses \\
\(* * * p<0.01, * * \mathrm{p}<0.05, ~ *<0.1\) \\
\hline
\end{tabular}

According to the above overall regression results, under-five mortality rate changes or increases 0.4 percentages and 0.5 percentages, when coefficient of the female primary and secondary school level decreases by one unit. The statistical significance levels of these are lower than \(99 \%\). A child from getting immunization meals and improved water are 0.4 percentages and 0.3 percentages points less likely to die under the age of five. The statistical significance levels of
these are lower than \(90 \%\). The findings also indicate a strong effective and negative relationship between under-five mortality rate and these variables in these seventeen countries except the female tertiary school level. Therefore, we can conclude that indeed female tertiary school enrollment by increasing has helped in decreasing under-five mortality rate in these seventeen developing countries in South East Asia and to this effect female tertiary school enrollment has been very effective especially by model-4.

\section*{V. DISCUSSION}

Hence above chapters present the deliveries of the study sample by designated demographic, socio-economic and community related characteristics which could either directly and/or indirectly affect under-five child mortality. The demographic and socio-economic characteristics especially mothers' educational levels can affect child mortality where children are born and upraised are vital and necessary to be lectured first before embarking on the study of any component of population change (be it fertility, mortality). The study population will improve good and clear sympathetic of the findings.

According to the reflection from my supervisors and research project evaluation result, they evaluated my thesis that the study explores critical topic in developing countries, that is, a relationship between mother's education and it impact on mortality rate. Mobilizing empirical data, the thesis investigate a magnitude of mother's education, as an independent variable, on the mortality and finds out positive relations between the two variables, which leads to a conclusion of 'mother is school'. Overall, the study is well organized and informative for future studies.

Finally, we accept this hypothesis due to panel data analysis that under-five child mortality is associated with mothers' educational levels than other factors in South East Asia's developing countries.

\section*{VI. CONCLUSION}

This study measures effects of mothers' education on under-five children mortality from developing countries in South East Asia. In order to prove the hypothesis, this study applied statistical analysis such as Hausman test with panel data and pooled OLS regressions by using three models. The results of my study discovered that the effects are all statistically significant.

My study confirmed a strong association between mother's education and under-five child mortality and remained significant after control for other factors. The findings of this paper supported for an independent effect of mother education levels ( primary, secondary and tertiary) operating through increase health knowledge such as improved water source, sanitation facilities, immunization and etc. for under-five child mortality rate.

Therefore, the findings of this research agree that "Mother is school". Most of developing countries in South East Asia show higher under-five mortality rate by low-level female education. This study can realize mothers' educational levels can appear to possess a stronger effect on the under-five child mortality rate than other factors.

This also can prove the effect of mothers' education on the under-five mortality developing countries in South East Asia. That is why; we can reduce under-five child mortality by improving the performance of female education in these regions. Countries with higher level of education can create the inclusive growth.
